

## Application in COSMOS

In the **COSMOS** project, the CRISPR/Cas9 tool is used to introduce mutations in specific genes involved in fatty acid and glucosinolate biosynthesis in oil crops. The aim is to improve the seed oil and seed meal quality of the two industrial oil crops camelina and crambe. This entails the creation of high levels of mono-unsaturated fatty acids, optimisation of fatty acid profiles and the reduction of Anti-Nutritional Factors (ANF) such as glucosinolates.

The creation of high mono-unsaturated fatty acid profiles means that the financial yield per hectare can be increased. The reduction of ANF enables dual use of the crops: the seeds can be pressed for the oil while the press cake, which contains the protein, can be used as feed, leading to an increased availability of domestic feed.

The COSMOS project has received funding from the European Union's Horizon 2020 research and information programme under grant agreement No. 635405.

# What is CRISPR/Cas9 and how is it used in the COSMOS project?

CRISPR/Cas9 has been making headlines throughout the media in the recent years as a new genome editing tool to speed up the breeding of crops and animals and even as a tool to cure diseases. But what is CRISPR/Cas9 actually and what are the genetic effects? This leaflet explains what CRISPR/Cas9 is and how this tool is used in the **COSMOS** project.

## Description of the technology

In bacteria, the CRISPR/Cas system provides resistance to viral infections. Based on the genetic information of previous infections, the CRISPR/Cas is able to cut the DNA of the invading virus in a very precise and effective way, thereby inactivating the virus.

CRISPR stands for Clustered Regularly Interspaced Short Palindromic Repeats and was identified in bacteria as part of their defence system against viruses, while Cas stands for CRISPR associated system. In the case of Cas9, it refers to CRISPR associated protein 9.

Molecular scientists discovered that this system could also work in plants, animals and even humans. It was found that the CRISPR part of the system (the DNA targeting device) could be modified in such a way that it targets a DNA sequence of choice after which the Cas9 protein cuts the DNA like a scissor at exactly that position. A specific DNA break is the result of this action. Interestingly, plant and animal cells have a system to repair such breaks, but upon repairing, a little stretch of DNA is either inserted or deleted. In this way, molecular biologists are able to knock out a gene (deletion of a small part of the DNA) or to add a new gene (insertion of a DNA fragment).

Because of its simplicity and precision, CRISPR/Cas9 has become a versatile tool in molecular biology to change the properties of the plant or animal cells.

The COSMOS project focusses on the deletion of a small part of a gene in plants using the CRISPR/Cas9 system. Such a small modification in a gene is called a mutation. Introduction of mutations is a technique widely used in traditional plant breeding – in these cases introduced in the genome by radiation or chemical treatment. In comparison with traditional mutation breeding tools, CRISPR provides very high precision in the position of mutations as it targets genes of interest only, while traditional mutation breeding tools cause random mutations not only in the target gene. Consequently, the time needed for creating a new plant with a specific mutation is much shorter when the CRISPR system is used.

## The legal issue

The CRISPR mutation system can be introduced in plant cells in different ways, but most efficiently today using genetic modification (GM) to introduce the CRISPR system itself in the first phase. The CRISPR system can then easily be removed using crossing after it has done its job in a second phase. The final plants contain the desired change in DNA (a mutation) but not the CRISPR system anymore.

The application of CRISPR/Cas9 in plants has raised a debate on the legal status of these plants: Should these plants be considered being a genetically modified organism (GMO) or not?

The use of genetic modification is regulated in EU Directive 2001/18/EC. This Directive contains a list of breeding techniques (such as transgenesis) of which the resulting plants are considered GMO and these GMO are subject to strict regulations. Traditional breeding including traditional mutation breeding is not subject to the strict GMO regulations because of a history of safe use. CRISPR mutants made in the way described before do not contain the transgenic CRISPR elements since these were removed by crossing. Therefore, as long as no foreign genes are introduced, CRISPR mutants do not contain transgenes. However, the EU Directive considers a plant or animal to be genetically modified when genetic modification was part of the process of making it, even when the transgenic element is no longer present in the final product.

It is clear that if foreign genes have been introduced using CRISPR the product is considered a GMO. However, CRISPR enhanced plants without foreign genes could be regarded at least as safe as products of traditional mutation breeding. In fact, CRISPR can be used to create the same functional mutation without causing the additional random mutations occurring with traditional mutation breeding.

As of October 2017, the European Commission has not taken a stance yet on whether CRISPR should necessarily be seen as a standard mutation breeding technique (without strict regulation) or should be regulated as a GMO falling under the strict regulation scheme.
